(Received 24 March 2004; accepted 13 April 2005; published online 22 June 2005)

The equilibrium structures and physical properties of the $\bar{X}^1\Sigma^+$ linear electronic states, linear excited singlet and triplet electronic states of hydroboron monoxide (HBO) ($\bar{A}^1\Sigma^-$, $\bar{B}^1\Delta$, $\bar{c}^3\Sigma^+$, and $\bar{B}^3\Delta$) and boron hydroxide (BOH) ($\bar{A}^1\Sigma^+$, $\bar{B}^1\Pi$, and $\bar{c}^3\Pi$), and their bent counterparts (HBO $\bar{a}^3\Delta'$, $\bar{A}^3\Delta'$, $\bar{b}^3\Delta'$, $\bar{b}^1\Pi'$ and BOH $\bar{A}^1\Sigma'$, $\bar{b}^3\Delta'$, $\bar{c}^3\Delta'$, $\bar{A}^1\Pi'$, $\bar{B}^1\Pi'$, $\bar{C}^1\Pi'$) are investigated using excited electronic state ab initio equation-of-motion coupled-cluster (EOM-CC) methods. A new implementation of open-shell EOM-CC including iterative partial triple excitations (EOM-CC3) was tested. Coupled-cluster wave functions with single and double excitations (CCSD), single, double, and iterative partial triple excitations (CC3), and single, double, and full triple excitations (CCSDT) are employed with the correlation-consistent quadruple and quintuple zeta basis sets. The linear HBO $\bar{X}^1\Sigma^+$ state is predicted to lie 48.3 kcal mol$^{-1}$ (2.09 eV) lower in energy than the BOH $\bar{X}^1\Sigma^+$ linear stationary point at the CCSDT level of theory. The CCSDT BOH barrier to linearity is predicted to lie 3.7 kcal mol$^{-1}$ (0.16 eV). With a harmonic zero-point vibrational energy correction, the HBO $\bar{X}^1\Sigma^+\rightarrow$BOH $\bar{X}^1\Sigma^+$ energy difference is 45.2 kcal mol$^{-1}$ (1.96 eV). The lowest triplet excited electronic state of HBO, $\bar{a}^3\Delta'$, has a predicted excitation energy ($T_e$) of 115 kcal mol$^{-1}$ (4.97 eV) from the HBO ground state minimum, while the lowest-bound BOH excited electronic state, $\bar{b}^3\Delta'$, has a $T_e$ of 70.2 kcal mol$^{-1}$ (3.04 eV) with respect to BOH $\bar{X}^1\Sigma^+$. The $T_e$ values predicted for the lowest singlet excited states are $\bar{A}^1\Pi''\rightarrow\bar{X}^1\Sigma^+=139$ kcal mol$^{-1}$ (6.01 eV) for HBO and $\bar{A}^1\Pi''\rightarrow\bar{X}^1\Pi'+=102$ kcal mol$^{-1}$ (4.42 eV) for BOH. Also for BOH, the triplet vertical transition energies are $\bar{b}^3\Pi'\rightarrow\bar{X}^1\Pi'+'=71.4$ kcal mol$^{-1}$ (3.10 eV) and $\bar{c}^3\Pi''\rightarrow\bar{X}^1\Pi'+'=87.2$ kcal mol$^{-1}$ (3.78 eV). © 2005 American Institute of Physics. I. INTRODUCTION

Hydroboron monoxide (HBO) is an intermediate or by-product of many reactions involving boron compounds.1–4 Boron-containing compounds are candidates for fuel additives5,6 and solid propellants that can increase rocket motor efficiency,7,8 HBO and its isomer boron hydroxide (BOH) have long been targets of experimental and theoretical studies. In the mid-1960s, HBO was first observed in the trimeric gas-phase form, boroxine (H$_2$B$_2$O$_3$), as a product of high-energy9,10 and combustion reactions.11 Shortly thereafter, Lory and Porter identified monomeric HBO in an argon matrix and reported its vibrational frequencies.12

The first theoretical study on the HBO/BOH system was performed by Thomson and Wishart13 in 1974. It was concluded from a Mulliken population analysis14 that HBO has an unusual B–O bond order between two and three, demonstrating an electron-deficient boron center. In 1977, Summers and Tyrrell15 reported a Hartree–Fock study of isoelectronic 14-electron species, determining the equilibrium geometry of linear BOH to have a higher energy than that of linear HBO. In 1979 Zyubina et al.16 were the first to analyze a potential-energy surface (PES) of the isomerization from HBO to BOH and noted some similarity to the PES for the isoelectronic linear HCN→HNC isomerization.17 Unlike HCN/HNC, when polarization functions were included in the basis set, a local minimum for bent BOH was discovered at $\angle BOH=125^\circ$ lying 4.1 kcal mol$^{-1}$ lower in energy than that for linear BOH. As such, BOH is an unusual violator of the Walsh–Mulliken qualitative molecular orbital (MO) rules for 14-electron systems.18–23

In 1986, the first gas-phase detection of monomeric HBO by Hirota’s group using the discharge modulation technique renewed interest in the electronic structure of HBO.24–26 Infrared and microwave spectroscopy confirmed a

linear HBO structure and provided gas-phase vibrational frequencies and rotational spectra. These experimental studies were followed by theoretical papers analyzing linear and bent ground states using correlated methods such as Møller–Plesset perturbation theory,\textsuperscript{27–29} coupled-cluster,\textsuperscript{30} and quadratic configuration interaction.\textsuperscript{31–33} These studies predicted the energy difference between the two isomers to be in a range of 44–51 kcal mol\textsuperscript{-1} and a HBO→BOH isomerization reaction barrier-height range of 71–80 kcal mol\textsuperscript{-1}.

In 1995, Gole and Michels\textsuperscript{31} provided isomerization PESs for the ground states and lowest \( ^3A' \) states of HBO and BOH using quadratic configuration interaction with single and double excitations and a perturbative triples correction [QCISD(T)]. They speculated that if crystalline BOH could be created, it might be able to release considerable energy upon controlled photochemical activation to excited electronic states and subsequent radiative relaxation to ground state HBO. At the \( \angle \text{BOH} \) angle of 53.0°, near where the first \( ^3A' \) isomerization transition state (TS) is expected to be found, the ground state BOH PES is still fairly shallow. If this system is promoted from ground state BOH to a vibrationally excited level of the first \( ^3A' \) state with a photon energy of \( \sim 3.7 \) eV, BOH may be able to undergo facile cyclic interconversion. If BOH is in fact a possible high-energy density material (HEDM),\textsuperscript{34–37} the hypothesis of Gole and Michels would be novel.

The 1999 study by Boldyrev and Simons\textsuperscript{32} focused on the HBO and BOH cations and reported not only that the \( \tilde{X}^1\Sigma^+ \) HBO→\( \tilde{X}^2\Pi \) HBO\textsuperscript{+} adiabatic ionization energy of 13.2 eV is far higher than that of BOH (9.6 eV), but also that BOH\textsuperscript{+} had a linear ground state (\( \tilde{X}^2\Sigma^+ \)) rather different from HBO\textsuperscript{+}’s. These differences originate from the large energy gap of the \( \pi \)-highest occupied molecular orbital (HOMO)/\( \pi \)-lowest unoccupied molecular orbital (LUMO) of HBO versus the small \( \sigma \)-HOMO/\( \sigma \)-LUMO energy gap of BOH.

A recent (2004) theoretical study conducted by Peng et al.\textsuperscript{38} recognized the need to use multireference methods to appropriately ascertain the wave functions of HBO/BOH excited electronic states. Energy points on the isomerization PESs were obtained for the first two HBO/BOH triplet states using second-order multireference Brillouin–Wigner perturbation theory (MRBWPT2) and the correlation-consistent polarized valence triple zeta (cc-pVTZ) basis sets. Peng et al. reported a ground-state isomer energy difference (54.4 kcal mol\textsuperscript{-1}) that was 4 kcal mol\textsuperscript{-1} higher than those of previous coupled-cluster studies.\textsuperscript{30}

Though the singlet-triplet excitations investigated in Refs. 31 and 38 are of a spin-forbidden nature, if enough intensity borrowing is available from nearby singlet excited states, the singlet-triplet electronic transition would possess an appreciable oscillator strength\textsuperscript{39} and the mechanism proposed by Gole and Michels could be possible. While a singlet-singlet BOH electronic transition would have a large oscillator strength, its lifetime would be orders of magnitude shorter than that of a singlet-triplet transition. In this situation, the BOH molecule would likely fluoresce back to its ground state before isomerization towards a strongly exothermic reaction pathway could occur. Although Gole and Michels have outlined explicit recipes for synthesizing and characterizing BOH,\textsuperscript{31} that research has not yet been experimentally realized.

To our knowledge, there are no published reports detailing the isomerization PESs of the HBO and BOH singlet excited electronic states. A more accurate theoretical prediction of excitation energies would validate the possibility of intensity borrowing between the BOH \( \tilde{A}^1A'/\tilde{A}' \) states for the proposed HEDM pathway. Our task in this research is to examine some low-lying singlet and triplet excited states of HBO and BOH using excited state coupled-cluster techniques.

II. ELECTRONIC STRUCTURE CONSIDERATIONS

The electronic configuration of \( \tilde{X}^1\Sigma^+ \) HBO is qualitatively described as

\[
|\text{core}|3\sigma^24\sigma^25\sigma^21\pi^4, \quad \tilde{X}^1\Sigma^+_{\text{HBO}}.
\]

The symbol [\text{core}] pertains to the occupied 1s-like oxygen and boron orbitals. The ground electronic configuration of the linear BOH molecule is expressed, noting that the 1\( \pi \) orbital is lower in energy than the 5\( \sigma \) orbital,

\[
|\text{core}|3\sigma^24\sigma^21\pi^45\sigma^2, \quad \tilde{X}^1\Sigma^+_{\text{BOH}}.
\]

For the bent ground state of BOH, the occupied 1\( \pi \) orbital of linear BOH splits into the 5\( \sigma' \) and 1\( \sigma'' \) MOs.\textsuperscript{40} The 5\( \sigma' \) orbital is more stabilized than the 1\( \sigma'' \) orbital, a result opposite to the prediction from Walsh diagrams.\textsuperscript{18} The bent electronic configuration is expressed as

\[
|\text{core}|(3\alpha')^2(4\alpha')^2(5\alpha')^2(1\alpha'')^2(6\alpha'')^2, \quad \tilde{X}^1A'.
\]

For linear HBO and BOH, the manifold of singly excited electronic states arises from the following types of electronic excitation:

(a) Promotion of a 1\( \pi \) electron to one of the antibonding 2\( \pi \) orbitals. Six excited electronic states can be derived from this single excitation,

\[
|\text{core}|3\sigma^24\sigma^25\sigma^21\pi^32\pi, \quad 1\Delta, 1\Sigma^-, 1\Sigma^+, 3\Delta, 3\Sigma^-, 3\Sigma^+.\]

(b) Promotion of a 5\( \sigma \) electron to one of the antibonding 2\( \pi \) orbitals. Two excited electronic states can be derived from this excitation,

\[
|\text{core}|3\sigma^24\sigma^25\sigma^11\pi^42\pi, \quad 1\Pi, 3\Pi.\]

(c) Promotion of a 1\( \pi \) electron to the 6\( \sigma \) antibonding MO, whereupon there are two excited electronic states,

\[
|\text{core}|3\sigma^24\sigma^25\sigma^11\pi^36\sigma, \quad 1\Sigma^+, 1\Pi, 3\Pi.\]

(d) Promotion of a 5\( \sigma \) electron to the 6\( \sigma \) MO, with the following two excited electronic states:

\[
|\text{core}|3\sigma^24\sigma^25\sigma^11\pi^46\sigma, \quad 1\Sigma^+, 2\Sigma^+.\]

Thus, there are thirteen unique linear electronic states relevant to this study, including the ground electronic state.
The electronic configuration for the $^1\Delta$ state from 1π → 2π excitation in real MO notation requires four Slater determinants. In $C_{2v}$ point-group symmetry notation, where the linear molecule is in the Cartesian z axis, its $A_1$ and $A_2$ components are, in the simplest picture,

$$[\text{core}]3\sigma^24\sigma^55\sigma^2 \times [(1\pi,\alpha(1)(2\pi,\beta(2)))1\pi_z^2$$

$$- (1\pi,\beta(1))(2\pi,\alpha(2))1\pi_y^2$$

$$- (1\pi,\alpha(1))(2\pi,\beta(2))1\pi_x^2$$

$$+ (1\pi,\beta(1))(2\pi,\alpha(2))1\pi_z^2], 1\Delta(A_1).$$

and

$$[\text{core}]3\sigma^24\sigma^55\sigma^2 \times [(1\pi,\alpha(1)(2\pi,\beta(2)))1\pi_z^2$$

$$- (1\pi,\beta(1))(2\pi,\alpha(2))1\pi_y^2$$

$$+ (1\pi,\alpha(1))(2\pi,\beta(2))1\pi_x^2$$

$$- (1\pi,\beta(1))(2\pi,\alpha(2))1\pi_z^2], 1\Delta(A_2).$$

The $^1\Sigma^-$ excited state requires four Slater determinants for a proper description and is written in terms of real orbitals as

$$[\text{core}]3\sigma^24\sigma^55\sigma^2 \times [(1\pi,\alpha(1)(2\pi,\beta(2)))1\pi_z^2$$

$$- (1\pi,\beta(1))(2\pi,\alpha(2))1\pi_y^2 - (1\pi,\alpha(1))$$

$$\times (2\pi,\beta(2))1\pi_x^2$$

$$+ (1\pi,\beta(1))(2\pi,\alpha(2))1\pi_z^2], 1\Sigma^-(A_2).$$

The open-shell $^1\Sigma^+$ wave function derived from the 1π → 2π excitation is qualitatively described as

$$[\text{core}]3\sigma^24\sigma^55\sigma^2 \times [(1\pi,\alpha(1)(2\pi,\beta(2)))1\pi_z^2$$

$$- (1\pi,\beta(1))(2\pi,\alpha(2))1\pi_y^2$$

$$+ (1\pi,\alpha(1))(2\pi,\beta(2))1\pi_x^2$$

$$- (1\pi,\beta(1))(2\pi,\alpha(2))1\pi_z^2], 1\Sigma^+(A_1).$$

The two degenerate components of the $^3\Delta$ state are written as

$$[\text{core}]3\sigma^24\sigma^55\sigma^2 \times [(1\pi,\alpha(1)(2\pi,\alpha(2)))1\pi_z^2$$

$$- (1\pi,\alpha(1))(2\pi,\alpha(2))1\pi_y^2$$

$$+ (1\pi,\alpha(1))(2\pi,\alpha(2))1\pi_z^2], 1\Delta(A_1).$$

and

$$[\text{core}]3\sigma^24\sigma^55\sigma^2 \times [(1\pi,\alpha(1)(2\pi,\alpha(2)))1\pi_z^2$$

$$+ (1\pi,\alpha(1))(2\pi,\alpha(2))1\pi_z^2], 1\Delta(A_2).$$

The $^3\Sigma^-$ wave function is

$$[\text{core}]3\sigma^24\sigma^55\sigma^2 \times [(1\pi,\alpha(1)(2\pi,\alpha(2)))1\pi_z^2$$

$$- (1\pi,\alpha(1))(2\pi,\alpha(2))1\pi_y^2], 1\Sigma^-(A_2).$$

Lastly, the $^3\Sigma^+$ wave function from 1π → 2π single excitations is

$$[\text{core}]3\sigma^24\sigma^55\sigma^2 \times [(1\pi,\alpha(1)(2\pi,\alpha(2)))1\pi_z^2$$

$$+ (1\pi,\alpha(1))(2\pi,\alpha(2))1\pi_z^2], 1\Sigma^+(A_1).$$

From the 5σ → 2π single excitation, the $^1B_1$ component of the following $^1\Pi$ electronic state wave function can be described as

$$[\text{core}]3\sigma^24\sigma^52\sigma^4 \times [(5\sigma,\alpha(1))(2\pi,\beta(2))]$$

$$- (5\sigma,\beta(1))(2\pi,\alpha(2))], 1\Pi(^1B_1).$$

and its triplet $^3B_1$ counterpart is

$$[\text{core}]3\sigma^24\sigma^52\sigma^4 \times [(5\sigma,\alpha(1))(2\pi,\alpha(2))], 1\Pi(^3B_1).$$

Arising from the 1π → 6σ single excitation, the $^1B_1$ component of the $^1\Pi$ electronic state wave function can be described as

$$[\text{core}]3\sigma^24\sigma^52\sigma^4 \times [(1\pi,\alpha(1)(6\sigma,\beta(2)))1\pi_z^2$$

$$- (1\pi,\beta(1))(6\sigma,\alpha(2))1\pi_x^2], 1\Pi(^1B_1),$$

with the corresponding triplet $^3B_1$ wave function,

$$[\text{core}]3\sigma^24\sigma^52\sigma^4 \times (1\pi,\alpha(1))1\pi_z^2(6\sigma,\alpha(2)), 1\Pi(^3B_1).$$

Finally, the wave functions of the two excited states owing to the 5σ → 6σ single excitation are written as

$$[\text{core}]3\sigma^24\sigma^52\sigma^4 \times [(5\sigma,\alpha(1))(6\sigma,\beta(2))]$$

$$- (5\sigma,\beta(1))(6\sigma,\alpha(2)]], 1\Sigma^+(A_1)$$

and

$$[\text{core}]3\sigma^24\sigma^52\sigma^4 \times [(5\sigma,\alpha(1))(6\sigma,\alpha(2))], 1\Sigma^+(A_1).$$

When the HBO and BOH linear isomers are bent, differences in their electronic structure create separate correspondence between their MOs of $C_{2v}$ and $C_1$ point-group symmetry. Translation of the $C_{2v}/C_{2v}$ MOs of HBO and BOH into $C_1$ symmetry is shown in Table I and the wave functions of possible bent singly excited electronic states are listed in Supplementary Table S1.41

### III. THEORETICAL METHODS

For single-reference methods, the zeroth-order description of $\tilde{X}^1\Sigma^+$ HBO and $\tilde{X}^1\Sigma^+$ BOH was obtained using restricted Hartree–Fock (RHF) wave functions. The zeroth-order descriptions of triplet states for coupled-cluster references were obtained with unrestricted HF (UHF) wave functions. Ground state dynamical correlation was accounted for using coupled-cluster methods,42–43 with single and double excitations (CCSD),44 single, double, and perturbative partial triple excitations (CCSD(T)),45 46 single, double, and iterative partial triple excitations (CC3),47 and full triple excitations (CCSDT).48, 49 For the excited electronic states, we
have made use of the equation-of-motion CCSD (EOM-CCSD)\textsuperscript{50,51} method as well as the CC3 model, which includes connected triple excitations. Although CC3 excitation energies are usually viewed from a linear-response perspective,\textsuperscript{52} we will use the EOM designation for both CCSD and CC3 excited states for the sake of simplicity.

The correlation-consistent polarized valence quadruple zeta (cc-pVQZ) basis sets developed by Dunning and coworkers were used in this study.\textsuperscript{53,54} Unless otherwise noted, in all correlated procedures the core 1s-like orbitals of oxygen and boron were frozen. Closed-shell and excited singlet state CC/EOM-CC computations were carried out using ACES II.\textsuperscript{55} The open-shell triplet CC3, EOM-CCSD, and EOM-CC3 methods were employed in conjunction with the PSI 3.2 package.\textsuperscript{56} The open-shell implementation of the CC3 and EOM-CC3 methods incorporated in PSI 3.2 were recently described in Ref. 56.

Structural optimizations and vibrational analyses were carried out at each level of theory using finite differences of energies. For $\tilde{X}^1\Sigma^+$ HBO and $\tilde{X}^1\Delta$ BOH, fundamental vibrational frequencies were also determined at the CCSD(T) level of theory (with all electrons correlated due to program requirements) using second-order vibrational perturbation theory with cubic and semidiagonal quartic force constants computed via finite differences of analytic second derivatives using the method described by Stanton et al.\textsuperscript{57}

Explicitly for linear HBO, the stationary points of the following electronic states were investigated: the $\tilde{X}^1\Sigma^+$ ground state, the $1^1\Sigma^+$ state, the $1^1\Delta$, the $1^3\Sigma^+$ state, and the $1^3\Delta$, which all arise from the $1\pi\rightarrow 2\pi$ excitation. For BOH, the electronic states included were the $\tilde{X}^1\Sigma^+$ ground state, the $3^3\Sigma^+$ and $1^1\Sigma^+$ states from the $5\sigma\rightarrow 6\sigma$ excitation, and the $3^1\Pi$ and $3^1\Delta$ states from the $5\sigma\rightarrow 2\pi$ excitation. Tables I and S1 describe the wave functions for the bent counterparts of electronic states under investigation, and the state ordering of the bent states will be discussed below. The minima of the highest-lying HBO and BOH excited states characterized are 5.8 and 3.2 eV below the ionization potential,\textsuperscript{32} respectively. It is not likely that Rydberg excited states exist within these manifolds of electronic states.

IV. RESULTS AND DISCUSSION

A. Linear ground state of HBO

The total energies, equilibrium geometries, and physical properties of the linear singlet ground electronic states of HBO and BOH are reported in Table II. The equilibrium bond lengths of $\tilde{X}^1\Sigma^+$ HBO have been experimentally determined by gas-phase microwave spectroscopy to be $r_e$(HB) = 1.1667±0.0004 Å and $r_e$(BO) = 1.2007±0.0001 Å.\textsuperscript{23,26} Coupled-cluster methods including triple excitations [CC3, CCSD(T), and CCSDT] reproduce the equilibrium geometry. The CCSD(T) $r_e$(BO) of 1.2019 Å is only 0.0012 Å longer than the derived gas phase $r_e$(BO). With the boron and oxygen 1s electrons correlated, the CCSD(T) geometries may represent a Pauling point for this electronic state. However, the frozen-core CC3 and CCSDT methods perform admisibly, and we prefer levels of theory with the core electrons frozen for the study of excited electronic states.

The CCSDT dipole moment of linear HBO has a magnitude of 2.70 D, with direction "HBO". The large dipole moment implies a highly polar molecule. The harmonic $\omega_1(\sigma)$ BH stretching frequencies obtained using the CCSD(T), CC3, and CCSDT methods are 2899, 2885, and 2890 cm\textsuperscript{-1}, respectively. In the analysis performed by Kawashima et al.\textsuperscript{26} the observed fundamental $\nu_3(\pi)$ and $\nu_3(\sigma)$ frequencies were used as harmonic frequencies in order to estimate the harmonic $\omega_1(\sigma)$ BH stretching frequency, which may explain their rather low $\omega_1(\sigma)$ value of 2821 cm\textsuperscript{-1}. Using the all-electron CCSD(T) anharmonic correction, the fundamental $\nu_3(\sigma)$ frequency is shifted to 2810 cm\textsuperscript{-1}, in fair agreement with the more reasonable estimated value of 2849±10 cm\textsuperscript{-1} given by Lory and Porter\textsuperscript{12} in their IR matrix-isolation experiments. The CCSD(T) fundamental $\nu_3(\pi)$ bending frequency of 759 cm\textsuperscript{-1} and the $\nu_3(\sigma)$ BO stretching frequency of 1831 cm\textsuperscript{-1} (computed with all electrons correlated, as noted above) are correct to within 5 cm\textsuperscript{-1} of the respective gas-phase fundamental frequencies. However, the inclusion of anharmonicity is seen to raise the $\nu_3(\pi)$ bending frequency, a highly unusual effect.

Relative to the full CCSDT result, the triples contribution of the CC3 method to the $\tilde{X}^1\Sigma^+$ HBO and $\tilde{X}^1\Sigma^+$ BOH total energies are overestimated by $\approx 1$ kcal mol\textsuperscript{-1}. However, CC3 geometries compare very favorably with the experimental and full CCSDT bond lengths, particularly in light of the computational savings offered.

B. Linear ground state of BOH

Table II shows energetic and geometric data for linear $\tilde{X}^1\Sigma^+$ BOH. The CCSDT geometry of $\tilde{X}^1\Sigma^+$ BOH is $r_e$(BO)=1.2791 Å and $r_e$(OH)=0.9493 Å. The BO distance of $\tilde{X}^1\Sigma^+$ BOH is longer than that of $\tilde{X}^1\Sigma^+$ HBO because of a lessening of $\pi$ overlap, and hence a weakening of the multiple bond character. This rather long BO bond is also an indicator of the preference towards a bent BOH minimum.

The CCSDT dipole moment of $\tilde{X}^1\Sigma^+$ BOH is larger than that of $\tilde{X}^1\Sigma^+$ HBO and of the opposite sign "BOH", with a magnitude of 3.69 D. The OH $\omega_1(\sigma)$ stretching frequency from the CC3 and CCSDT methods is 4009 and 4018 cm\textsuperscript{-1}, respectively, and the BO stretching frequency $\omega_3(\pi)$ is 1464 and 1473 cm\textsuperscript{-1}, respectively. Due to the elongated BO bond length, the $\omega_3(\sigma)$ frequency of $\tilde{X}^1\Sigma^+$ BOH is lower by approximately 360 cm\textsuperscript{-1} than the BO stretch of HBO. The bending frequency of $\tilde{X}^1\Sigma^+$ BOH is imaginary, signifying a bent equilibrium geometry for BOH. The imaginary CC3 and CCSDT $\omega_3(\pi)$ harmonic frequencies are 485i and 487i cm\textsuperscript{-1}.

The overestimation of the triple excitation contribution to the total energy using the CC3 method is largely canceled when considering relative energies. With all electrons correlated, the CCSD(T) energy separation between the linear ground states is predicted to be 49.2 kcal mol\textsuperscript{-1}. There is little effect due to core correlation on the harmonic zero-point vibrational energy (ZPVE), and the ZPVE-corrected energy difference between the HBO and BOH linear ground
states is predicted to be 48.9 kcal mol\(^{-1}\) with CC3 and 48.3 kcal mol\(^{-1}\) with CCSDT. The extension of the basis set to correlation-consistent polarized valence quintuple zeta \(cc-pV5Z\) at the CC3 \(cc-pVQZ\) geometries increases the separation by just 0.1 kcal mol\(^{-1}\). We are confident that the true energy difference between the linear isomers is near 48–49 kcal mol\(^{-1}\).

C. Bent BOH ground state

The bent \(\tilde{X}^1A'\) BOH equilibrium geometry of the ground state in Table III has been discussed in a number of theoretical papers.\(^{30,31,38,40}\) The CCSDT bond lengths for the bent BOH \(\tilde{X}^1A'\) state increase (compared to the linear structure) due to destabilization of the \(\pi\) bonding. The CSDT \(r_s(BO)\) prediction is 1.3051 Å, \(r_s(OH)\) is 0.9617 Å, and the BOH angle is 121.4°. Harmonic vibrational frequencies are similar to the BOH linear structure and the stretching frequencies are predicted to be \(\nu_1(a') = 3855\) cm\(^{-1}\) and \(\nu_2(a') = 1402\) cm\(^{-1}\), while the \(\nu_3(a')\) BOH angle bend is predicted to be 619 cm\(^{-1}\). The theoretical rovibrational study of HBO/BOH performed by Ha and Makarewicz\(^{29}\) in 1999 sampled the PES of the \(\tilde{X}^1A'\) BOH state and presented evidence that the harmonic approximation will fail due to large amplitude motion of the hydrogen nucleus around the BO bond. Indeed, the anharmonic corrections to the vibrational frequencies shift the values of the O–H stretching and BOH-angle bending significantly, as the all-electron CCSD\(^{\ast}\) level of theory predicts the fundamental \(\nu_1(a')\) to be 3679 cm\(^{-1}\), \(\nu_2(a')\) to be 1399 cm\(^{-1}\), and the bending \(\nu_3(a')\) to be 563 cm\(^{-1}\). The CCSD\(^{\ast}\) fundamental vibrational frequencies obtained in our study are larger than the MP2 fundamental vibrational frequencies of Ha and Makarewicz\(^{29}\) by 37 and 57 cm\(^{-1}\), respectively. Hopefully the rovibrational parameters fit by Ha and Makarewicz and our improved fundamental vibrational frequencies will assist in the spectroscopic identification of the BOH ground state.

At the CSDT level of theory, the \(\tilde{X}^1A'\) BOH minimum is predicted to be lower in energy than the linear stationary point by 3.7 kcal mol\(^{-1}\). With the harmonic ZPVE correction, the energy difference between the \(\tilde{X}^1S^+\) HBO and \(\tilde{X}^1A'\) BOH ground states is 45.2 kcal mol\(^{-1}\). The CSDT and CC3 methods are again in good agreement for the geometry and energetics, whereas the differences in quantities between CSDT and CCSD shown in Table III are somewhat larger. It seems evident that the CC3 method is more reliable than

CCSD for the HBO/BOH system, and it is expected that such accuracy can be translated to the EOM-CC3 predictions for the excited electronic states.

D. Linear HBO singlet excited states

The total energies and physical properties of the linear excited states are presented in Table IV. The two lowest-lying linear singlet excited states of HBO are the \( \tilde{A}\tilde{1}S^− \) and \( \tilde{B}\tilde{1}D^+ \) states, formed from \( 1\pi \rightarrow 2\pi \) excitation. As the two states possess the same dominant electronic configuration with different configuration state functions, their relative energies and geometries are similar. For both states, the \( 1\pi \rightarrow 2\pi \) excitation greatly increases the B–O bond distance relative to the ground state. At the EOM-CC3 level, the \( \tilde{A}\tilde{1}S^− \) B–O bond distance is predicted to be 1.4219 Å, and that of the \( \tilde{B}\tilde{1}D^+ \) state \( r_e(BO) \) to be 1.4276 Å, implying a weak BO bond for both states. Higher in energy, the \( \tilde{B}\tilde{1}D^+ \) state has the weaker and slightly longer BO bond. Since electrons involved in the \( \pi \rightarrow \pi^* \) excitation of these two states are localized on the boron and oxygen atoms, the EOM-CC3 HB bond distances of the first two singlet excited states remain within 0.003 Å of the \( \tilde{X}\tilde{1}S^+ \) HBO value of \( r_e(HB) \). Compared to the EOM-CC3 bond length, the EOM-CCSD method provides a reasonable \( r_e(HB) \) for the HBO singlet excited states, but underestimates \( r_e(BO) \) by nearly 0.03 Å.

$^a$The dipole direction of the $\tilde{A} \Sigma^+$ state is “BOH”, whereas the dipole direction of the $\tilde{B} \Pi$ and $\tilde{b} \Pi$ states is “BOH$^+$. $^b$Energy differences are relative to the optimized $\tilde{X} \Sigma^+$ BOH structure. $^c$Due to the Renner–Teller splitting, the $a'$ and $a''$ components of the $\omega_s(\pi)$ harmonic vibrational frequency are nondegenerate. The $a''$ component is listed in parentheses. $^d$Reference 31. $^e$Relative energies from Ref. 31 are obtained with 6-311+G(d,p) QCISD(T) single points at the 6-311+G(d,p) QCISD optimized geometry. $^f$Reference 38.

The EOM-CCSD dipole moment of the $\tilde{A} \Sigma^-$ state is 0.84 D, while the dipole moment of the $\tilde{B} \Delta$ state is 0.94 D. Charge localization on the boron atom (compared to the $\tilde{X} \Sigma^+$ ground state) reduces the magnitude of the $\tilde{A} \Sigma^-$ and $\tilde{B} \Delta$ dipole moments by a factor of three but retains the “HBO$^+$” dipole direction. As the HB bond distance for these two states is in a range similar to the ground state, the EOM-CC3 HB stretching ($\omega_d$) frequency has a similar value; 2882 cm$^{-1}$ for the $\tilde{A} \Sigma^-$ state and 2880 cm$^{-1}$ for the $\tilde{B} \Delta$ state. Inclusion of triple excitations with the EOM-CC3 wave function reduces the value of $\omega_d(\sigma)$ by more than 100 cm$^{-1}$ compared to the EOM-CCSD method, with $\omega_d(\sigma)$ =1095 cm$^{-1}$ for $\tilde{A} \Sigma^-$ and 1072 cm$^{-1}$ for $\tilde{B} \Delta$. This trend generally continues among the investigated linear triplet excited states of HBO, as the triple excitations are crucial in properly describing the weak BO $\pi$ bonding. Both excited electronic states have imaginary bending frequencies, 974i and 954i cm$^{-1}$, indicating respective bent equilibrium geometries.

E. Linear BOH singlet excited states

Energies, geometries, and physical properties of BOH linear excited states are presented in Table V. Preliminary computations of higher-lying $\Delta$ and $\Sigma^-$ BOH states, along with conclusions from the study of the BOH$^+$ cation, imply that the BOH $\pi \rightarrow \pi^*$ excitation is unfavorable and leads to some dissociated excited electronic states. The $\tilde{A} \Sigma^+$ BOH state comes from the 5$s$ nonbonding B atom lone pair being excited to the 6$s$ weakly OH antibonding MO, which tightens the BO bonding [$r_e$(BO)=1.202 Å] and creates a weaker OH bond [$r_e$(OH)=1.4451 Å]. The EOM-CCSD method performs less well for this excited state, with geometries differing from EOM-CC3 by 0.01–0.03 Å. The highly ionic $\tilde{A} \Sigma^+$ excited state contains significant contribution from both single and double 5$s$–6$s$ substitutions to the reference wave function, and EOM-CCSD fails to adequately describe this multireference character.

The dipole moment of the $\tilde{A} \Sigma^+$ state of BOH is predicted to be 1.47 D at the EOM-CCSD level of theory. Unlike other BOH excited states, the $\tilde{A} \Sigma^+$ BOH state has a dipole moment direction of “BOH$^-$. Single and double 5$s$–6$s$ excitations appear to shift enough charge density to change the direction of the dipole moment. The EOM-CC3 method yields an imaginary bending $\omega_d(\pi)$ frequency of 480i cm$^{-1}$, which implies a bent equilibrium geometry.

The $\tilde{B} \Pi$ state of BOH mainly involves single excitations from the reference coupled-cluster wave function, and thus EOM-CCSD and EOM-CC3 geometries agree more closely. The geometry and two harmonic vibrational stretching frequencies of the $\tilde{B} \Pi$ state are very similar to those of the BOH $\tilde{X} \Sigma^+$ ground state. While still large, the EOM-CCSD dipole moment of 2.79 D is smaller in magnitude...
than that of the BOH $\tilde{X}^1\Sigma^+$ ground state. The $5\sigma \rightarrow 2\pi$ excitation shifts the charge density from the nonbonding B-atom lone pair to the $\pi$-antibonding MOs centered on the boron and oxygen atoms. Therefore, the negative charge remains localized on the B and O atoms, and the dipole direction is the same as that for the $\tilde{X}^1\Sigma^+$ state, namely “BOH”. The harmonic bending vibrational frequencies for this state show a case (d) Renner–Teller splitting. The $a'$ mode $\omega_2(\pi)$ has an imaginary frequency of 1443 cm$^{-1}$ and the $a''$ mode has an imaginary frequency of 640i cm$^{-1}$. Both the $1A'$ and $1A''$ components resulting from the linear $\tilde{B}^3\Pi$ state should have nonlinear equilibrium geometries with the $1A'$ stationary point being lower in energy.

F. Linear HBO triplet excited states

Geometric parameters of the two HBO linear triplet excited states are shown in Table IV. Since $1\pi \rightarrow 2\pi$ excitation enhances BO antibonding and extends $r_c$(BO) by approximately 0.2 Å, the geometries of the two linear triplet HBO excited states resemble their singlet counterparts with the same electron configuration. The dipole moments of these two states point in the same direction as the corresponding HBO singlet states, but with smaller magnitudes. The $\tilde{a}^3\Sigma^+$ and $\tilde{b}^3\Delta$ harmonic vibrational stretching frequencies are similar, both with respect to each other and to the isoconfigurational linear $\tilde{A}^1\Sigma^+$ and $\tilde{B}^1\Delta$ states of HBO. At the EOM-CC3 level of theory, both linear triplet states have imaginary $\omega_2(\pi)$ harmonic frequencies. The $\tilde{a}^3\Sigma^+$ $\omega_2(\pi)$ bending frequency is $907i$ cm$^{-1}$ and the $\tilde{b}^3\Delta$ value of $\omega_2(\pi)$ is $993i$ cm$^{-1}$, indicating bent equilibrium geometries for both states.

G. Linear BOH triplet excited states

Since the BOH $\tilde{A}^1\Sigma^+$ electronic state arising from the $\sigma\rightarrow\sigma'$ excitation is lower lying than the $\tilde{B}^3\Pi$ state, it is expected that the triplet state arising from the $\sigma\rightarrow\sigma'$ HOMO-LUMO excitation will be the lowest-lying excited electronic state of BOH. This excited electronic state does exist; however, it dissociates at all levels of theory to the same asymptote (BO $\chi^2\Sigma^+$ radical$^{50,61} + ^2S$ H atom) as the BOH ground state. Its bent counterpart, the $\tilde{a}^3A'$ BOH electronic state, also dissociates to the BO $\chi^2\Sigma^+$ radical + $^2S$ H atom. Contrary to the proposed state ordering of Gole and Michels,$^{31}$ a consideration of this unbound (dissociative) excited electronic state allows us to label the first bound, linear triplet excited state of BOH as $\tilde{b}^3\Pi$, arising from the $5\sigma \rightarrow 2\pi$ excitation.

Geometries, dipole moments, and vibrational harmonic frequencies for the $\tilde{b}^3\Pi$ state are presented in Table V. This electronic state is well described by a single-reference coupled-cluster wave function, and higher accuracy is expected with the CC3 method compared to previous studies. Much like the $\tilde{B}^1\Pi$ state, the $\tilde{b}^3\Pi$ state qualitatively resembles the BOH ground state with a slightly extended $r_c$(BO) of 1.3142 Å and an $r_c$(OH) of 0.9417 Å. Contrary to the discussion of Peng et al.,$^{38}$ the first two bent triplet states of BOH connect to the same linear BOH $\tilde{b}^3\Pi$ state. The linear $3B_{1}/3B_{2}$ components of this $3\Pi$ state should give identical total energies and geometries when the BOH bond angle is constrained to 180°. We suspect that the use of two different active spaces to describe the $\tilde{b}^3A'$ and $\tilde{c}^3A''$ electronic states by Peng et al. leads to a qualitatively incorrect PES near BOH linearity, providing nondegenerate total energies.

The dipole moment of the $\tilde{b}^3\Pi$ state has the same sign as the BOH ground state with a value of 2.08 D. Harmonic vibrational frequencies for the BOH $\tilde{b}^3\Pi$ state are similar to those of the BOH $\tilde{B}^3\Pi$ state. Bending frequencies are both imaginary and again show class (d) Renner–Teller splitting, with the $a'$ $\omega_2(\pi)$ component having the larger imaginary frequency. The CC3 frequencies are $a'\omega_2(\pi)=1122i$ cm$^{-1}$ and $a''\omega_2(\pi)=523i$ cm$^{-1}$. The two bent electronic states should be minima, with the $3A'$ stationary point being lower in energy than the $3A''$ state, akin to the BOH $\tilde{B}^1\Pi$ electronic state.

It has been shown that spin contamination affects the quality of open-shell UHF coupled-cluster wave functions$^{62}$ and that the situation can be exacerbated when investigating open-shell excited states.$^{63}$ Szalay and Gauss surveyed a number of systems and found that “well-behaved” reference coupled-cluster wave functions led to nearly uncontaminated $\langle S^2 \rangle$ values for excited states.$^{63}$ However, to our knowledge the expected lessening of spin contamination with UHF EOM-CC3 (vis-à-vis UHF EOM-CCSD) has not yet been examined. In this investigation, almost all EOM-CC3 triplet excited state wave functions are computed using the closed-shell ground state as a “false-UHF” reference. Therefore the triplet states characterized with this method are exactly spin-adapted and should present no spin contamination. The exceptions to this are the $\tilde{b}^3\Pi$ BOH electronic state and the corresponding bent $\tilde{b}^3A'$ and $\tilde{c}^3A''$ BOH excited states. For these excited states, our reference $\langle S^2 \rangle$ values for the UHF HBO/BOH linear and bent triplet states are never greater than 2.01, close to the optimal $S(S+1)$ value of 2.00. Therefore, spin contamination does not appear to be a concern in this study.

H. Bent HBO excited states

Optimized geometries and harmonic vibrational frequencies for the four bent HBO excited electronic states ($\tilde{a}^3A'$, $\tilde{b}^3A''$, $\tilde{A}^1A''$, and $\tilde{B}^1A'$) are reported in Table VI. The geometries of the investigated singlet and triplet HBO bent excited states are similar, since they arise from the bending of isoconfigurational excited electronic states. The EOM-CC3 $r_c$(HB) of all four states ranges from 1.202–1.217 Å, which represents a slight elongation from the associated linear states. The $\tilde{a}^3A'$ state is predicted to have the shortest BO bond, $r_c=1.356$ Å, which is also the case for the corresponding HBO $\tilde{a}^1\Sigma^+$ linear structure. Akin to the linear singlet and triplet excited electronic state structures, the EOM-CC3 $r_c$(BO) values for the bent excited states are 0.012–0.030 Å.
longer than those obtained with EOM-CCSD. With a tighter BO bond and a weaker HB bond, the $a^3\Lambda'$ state has the smallest $\angle_{\text{HBO}}$ of 108.8°.

All harmonic vibrational frequencies for the $a^3\Lambda'$, $b^3\Lambda''$, $A^1\Lambda'$, and $B^1\Lambda'$ excited states are real, validating these bent structures as minima, and most harmonic vibrational frequencies resemble the values of their linear counterparts. As the $A\bigtriangleup_1\Delta$ state is higher in energy and possesses a smaller imaginary $\omega_2(\pi)$ frequency than the $A^1\Sigma^-$ state, the HBO $A\bigtriangleup_1\Delta$ state is formed from the $1\alpha'$ resolution of the $A^1\Sigma^-$ state and the $B^1\Lambda'$ state from the $A'$ component of the $B\bigtriangleup_1\Delta$ state. The $a^3\Lambda'$ state arises from the $3\alpha'$ resolution of the $a^3\Sigma^+$ state, and the $b^3\Lambda''$ state from the $3\Lambda''$ component of the $b^3\Delta$ state.

I. Bent BOH excited states

The equilibrium geometries and harmonic vibrational frequencies for the characterized bent BOH excited electronic states ($b^3\Lambda'$, $c^3\Lambda''$, $A^1\Lambda'$, $B^1\Lambda'$, and $C^1\Lambda''$) are presented in Table VII. The $A^1\Lambda'$ state has different geometric parameters from the other characterized BOH excited states, with an EOM-CC3 $r_c(BO)$ of 1.243 Å and an $r_c(OH)$ of 1.571 Å, suggesting a very loose OH bond. The inclusion of partial triple excitations into the EOM-CC wave function affects the geometry and relative energy of the BOH $A^1\Lambda'$ state, more so than other excited electronic states of HBO and BOH. As will be discussed below, the ground state BOH total energy rises sharply upon $r_c(OH)$ elongation, and it is expected that at the $A^1\Lambda'$ optimized geometry the ground state wave function contains multireference character as well, justifying the benefits of the EOM-CC3 method. An analysis of the MOs and the similarities between the BOH $A^1\Sigma^+$ and $A^1\Lambda'$ bond distances provide a convincing argument that the $A^1\Lambda'$ state is derived from the $1\Lambda'$ resolution of the $A^1\Sigma^+$ state, rather than the $1\Lambda'$ component of the $B^1\Pi$ state.

As noted, upon bending of either the BOH $b^1\Pi$ state or the $b^1\Pi$ state, Renner–Teller splitting necessarily forms non-degenerate electronic states. Since the $\omega_2(\pi)$ $a'$ component of the BOH $b^1\Pi$ state has a larger imaginary frequency than the $a''$ component, the $b^1\Lambda'$ state connected to the $b^1\Pi$ state lies energetically between the bent $A^1\Lambda'$ state and the $C^1\Lambda''$ state. The bond lengths and harmonic vibrational frequencies of all investigated BOH bent excited electronic states generally resemble their linear counterparts. The $b^1\Lambda'$, $c^3\Lambda''$, $A^1\Lambda'$, $B^1\Lambda'$, and $C^1\Lambda''$ excited electronic states of BOH each have three real harmonic vibrational frequencies, and thus each is a genuine minimum.

Figure 1 schematically depicts adiabatic transition energies relative to the linear HBO $\bar{X}^1\Sigma^+$ ground state, and all investigated excited electronic states show bent minima and a likely isomerization transition state (to BOH) at a $\angle_{\text{BOH}}$ of 40°–80°. The same qualitative “double-well” phenomenon as that of Gole and Michels31 and of Peng et al.38 is observed for the PES of the two lowest-lying triplet states. The electronic structure of the system changes dramatically in the region of the isomerization transition states, from preferential HBO $\pi \rightarrow \pi'$ character to BOH $\sigma \rightarrow \pi$ or $\sigma \rightarrow \sigma'$ character. As a consequence, the excited state isomerization PESs could connect different linear electronic states.
TABLE VII. Total energies and physical properties of bent BOH excited electronic states. [Energies are in hartrees, bond distance in angstrom, bond angles in degrees, harmonic vibrational frequencies in cm$^{-1}$, and adiabatic transition energies in kcal mol$^{-1}$ (eV, in parentheses) relative to the bent $\tilde{X}^1A'$ BOH ground state.] Note that the $\tilde{a}^1A'$ excited state dissociates to a BO $\tilde{X}^2\Sigma^+$ radical plus a $^1S$ H atom and is not presented in the table.

J. Adiabatic and vertical transition energies of excited states

The adiabatic transition energies of the stationary points are displayed in the last column of Tables III–VII and pictorially in Fig. 1. For HBO, the energetic EOM-CC3 $T_e$ ordering for minima found in this research is in kcal mol$^{-1}$.

\begin{align*}
0(\tilde{X}^1\Sigma^+) < 115(\tilde{a}^3A') < 132(\tilde{b}^3A') < 139(\tilde{A}^1A'') < 151(\tilde{B}^1A'),
\end{align*}

and the BOH energetic ranking is

\begin{align*}
0(\tilde{X}^1A') < 70(\tilde{B}^3A') < 86(\tilde{C}^3A') < 102(\tilde{A}^1A') < 128(\tilde{B}^1A') < 141(\tilde{C}^1A'').
\end{align*}

As expected, the smaller and highly geometry-dependent HOMO-LUMO gap of $\tilde{X}^1A'$ BOH brings about a denser cluster of BOH excited electronic states. Our adiabatic energies are in excellent agreement for those of the $\tilde{B}^3A'$ electronic state investigated by Gole and Michels.$^{31}$ However, while our HBO $T_e$ values agree with those of the Peng et al. study,$^{38}$ our BOH adiabatic transition energies are often 13–15 kcal mol$^{-1}$ larger. We suspect that their use of different active spaces for the $3A'$ and $3A''$ states may create an artificial lowering of the $3A''$ PES total energy. It is also possible that the MR-BWPT2 method does not recover enough dynamical correlation in the near-equilibrium region of the BOH $\tilde{X}^1A'$ ground state.
The CC3 $\tilde{b}^3A' \rightarrow \tilde{X}^1A'$ adiabatic $T_e$ for BOH is 3.04 eV, in agreement with the theoretical prediction of 2.99 eV by Gole and Michels,\textsuperscript{31} while the CC3 BOH $\tilde{c}^3A'' \rightarrow \tilde{X}^1A'$ adiabatic excitation energy is 3.71 eV. The vertical $\tilde{b}^3A' \rightarrow \tilde{X}^1A'$ transition energy is 3.10 eV with the CC3 method, and the $\tilde{c}^3A'' \rightarrow \tilde{X}^1A'$ vertical excitation energy is 3.81 eV, which is much larger than the prediction of $\sim3.05$ eV by Peng et al.\textsuperscript{38}

Because of the large geometric elongation of the OH bond length at the BOH $\tilde{A}^1A'$ excited state minimum (compared to that of the $\tilde{X}^1A'$ BOH ground state and (b) the equilibrium geometry of the $\tilde{A}^1A'$ BOH excited electronic state. The arrow connecting the two columns shows the difference of the $\tilde{X}^1A'$ ground-state energy (a) at its equilibrium geometry and (b) at the $\tilde{A}^1A'$ equilibrium geometry with an elongated OH bond.

The CC3 $\tilde{b}^3A' \rightarrow \tilde{X}^1A'$ adiabatic $T_e$ for BOH is 3.04 eV, in agreement with the theoretical prediction of 2.99 eV by Gole and Michels,\textsuperscript{31} while the CC3 BOH $\tilde{c}^3A'' \rightarrow \tilde{X}^1A'$ adiabatic excitation energy is 3.71 eV. The vertical $\tilde{b}^3A' \rightarrow \tilde{X}^1A'$ transition energy is 3.10 eV with the CC3 method, and the $\tilde{c}^3A'' \rightarrow \tilde{X}^1A'$ vertical excitation energy is 3.81 eV, which is much larger than the prediction of $\sim3.05$ eV by Peng et al.\textsuperscript{38}

Because of the large geometric elongation of the OH bond length at the BOH $\tilde{A}^1A'$ excited state minimum (compared to that of the $\tilde{X}^1A'$ BOH ground state and (b) the equilibrium geometry of the $\tilde{A}^1A'$ geometric equilibrium (with the OH bond significantly elongated), the ground state is much higher in energy, with an EOM-CCSD $\tilde{X}^1A'/\tilde{A}^1A'$ excitation energy of only 1.90 eV. Note that the ground-state energy required for such an $\eta$(OH) elongation is approximately 3.06 eV. Figure 2 indicates that the BOH ground state, the $\tilde{B}^1A'$ state, and the $\tilde{C}^1A''$ state all travel significantly “uphill” along the stretched OH bond coordinate.

The BOH $\tilde{X}^1A'$ equilibrium geometry resembles the geometries of the $\tilde{B}^1A'$ and $\tilde{C}^1A''$ excited electronic states more than that of the $\tilde{A}^1A'$ electronic state. Hence, the $\tilde{B}^1A'$ state has a lower EOM-CCSD vertical excitation energy (5.64 eV) than the $\tilde{A}^1A'$ state (7.12 eV). Due to the large shift in relative state energies along the potential-energy curve for $r_e$(OH) stretching, both conical intersections\textsuperscript{64–66} and avoided crossings occur. Along this stretching coordinate, there will be $\tilde{A}^1A'/\tilde{C}^1A''$ and $\tilde{B}^1A'/\tilde{C}^1A''$ conical intersections, as well as an $\tilde{A}^1A'/\tilde{B}^1A'$ avoided crossing. The mapping of PESs and such conical intersections may lend well to theoretical elaboration, but is outside the scope of this investigation.

Gole and Michels infer that for excitation intensity borrowing to be possible, the energy difference between the first excited singlet and lowest triplet BOH states at the $\tilde{X}^1A'$ BOH equilibrium geometry should be similar to the isoelectronic $\tilde{A}^1II/\tilde{A}^3II$ boron monofluoride vertical excitation energy difference of 2.73 eV.\textsuperscript{31} The computed CC3/EOM-CC3 vertical energy difference between the $\tilde{b}^3A' \rightarrow \tilde{X}^1A'/\tilde{B}^1A'$ electronic transitions is 2.78 eV. Our agreement with previous theoretical work and empirical observation sustains the possibility of singlet-triplet excited state intensity borrowing.

To function as a HEDM material, electronic excitation to a vibrationally excited triplet BOH state will be necessary to allow possible isomerization via the TS barriers in Fig. 1. However, dissociative HBO electronic states arising from the $\pi \rightarrow \sigma^*$ excitation and unbound BOH electronic states from the $\pi \rightarrow \pi'$ or $\pi \rightarrow \pi^*$ excitations may lie near the excitation energy of the highly vibrationally excited low-lying triplet states. Quanta absorbed into BOH stretching modes may break apart the molecule if the bent $\tilde{b}^3A'$ and $\tilde{c}^3A''$ PESs approach dissociative pathways.

V. CONCLUSIONS

The $\tilde{X}^1\Sigma^+$ HBO ground-state global minimum, the $\tilde{X}^1A'$ BOH ground state, and the linear $\tilde{X}^1\Sigma^+$ BOH transition state have been studied using \textit{ab initio} methods with the cc-pVQZ basis sets. Stationary points for the HBO $\tilde{A}^1\Sigma^+$, $\tilde{B}^1\Delta$, $\tilde{p}^1\Sigma^+$, and $\tilde{b}^1\Delta$ excited states as well as the BOH $\tilde{A}^1\Sigma^+$, $\tilde{B}^1\Pi$, and $\tilde{b}^1\Pi$ excited states and their bent counterparts have been characterized with a new implementation of excited state coupled-cluster theory (CC3). The harmonic vibrational frequency analyses of the linear and bent excited states indicate that all excited electronic states characterized here have bent minima.

This study provides the first consistent set of predictions for the singlet excited electronic states of HBO and BOH. The energy ordering of the bound minima are $\tilde{X}^1\Sigma^+ < \tilde{A}^1\Sigma' < \tilde{b}^3\Sigma' < \tilde{A}^3\Sigma' < \tilde{B}^1A'$ for HBO and $\tilde{X}^1A' < \tilde{b}^3A' < \tilde{c}^3A' < \tilde{B}^1A' < \tilde{C}^1A''$ for BOH. The $\tilde{A}^3A'$ HBO and $\tilde{b}^3A'$ BOH states are both $\sim115$ kcal mol$^{-1}$ (5.0 eV) higher in energy than $\tilde{X}^1\Sigma^+$ HBO. The lowest excited singlet states are $\tilde{A}^1A''$ for HBO, with a predicted $T_e$ of 139 kcal mol$^{-1}$ (6.01 eV) and $\tilde{A}^1A'$ for BOH, with a $T_e$ value of 148 kcal mol$^{-1}$ (6.40 eV). The HBO $\pi \rightarrow \pi^*$ excitation from the ground electronic state causes a lengthening of the BO bond and a lessening of the dipole moment magnitude, while the BOH $\sigma \rightarrow \sigma^*$ excitation severely lengthens.
the OH bond and causes a change in the direction of the dipole moment. On the other hand, the BOH $\sigma \rightarrow \pi^*$ excitation slightly elongates the BO bond and decreases the dipole moment.

The EOM-CC3 method is found to be more accurate than the EOM-CCSD method, especially for the two BOH excited states ($\tilde{a}^3A'$ and $\tilde{A}^1A'$) arising from the $\sigma \rightarrow \sigma^*$ excitation. The EOM-CC methods provide both closed- and open-shell excited electronic states total energies, geometric properties, and harmonic vibrational frequencies in a nearly “black box” manner. Singlet-triplet vertical and adiabatic transition energies are predicted at an accuracy that exceeds previous theoretical studies. Assuming the challenge of synthesizing and storing BOH in sufficient amounts is met, traversing the excited state isomerization PES of BOH to HBO may be treacherous due to dissociative excited electronic states along the proposed reaction pathway. Obviously, much more theoretical and experimental work must be carried out to test the viability of BOH as a high-energy density material.
